Eigenstate preparation is ubiquitous in quantum computing, and a standard approach for generating the lowest-energy states of a given system is by employing adiabatic state preparation (ASP). In the present work, we investigate a variational method for determining the optimal scheduling procedure within the context of ASP. In the absence of quantum error correction, running a quantum device for any meaningful amount of time causes a system to become susceptible to the loss of relevant information. Therefore, if accurate quantum states are to be successfully generated, it is crucial to find techniques that shorten the time of individual runs during iterations of annealing. We demonstrate our variational method toward this end by investigating the hydrogen and P4 molecules, as well as the Ising model problem on a two-dimensional triangular lattice. In both cases, the time required for one iteration to produce accurate results is reduced by several orders of magnitude in comparison to what is achievable via standard ASP. As a result, the required quantum coherence time to perform such a calculation on a quantum device becomes much less stringent with the implementation of this algorithm. In addition, our variational method is found to exhibit resilience against control errors, which are commonly encountered within the realm of quantum computing.

I. INTRODUCTION

It is widely recognized that attempts to realize solutions to computational problem sets involving quantum systems via classical hardware quickly give rise to intractable bottlenecks. This consequence becomes readily apparent as the amount of parameters required to describe the quantum state in question increases exponentially with growing system size. A commonly encountered manifestation of this phenomenon presents itself within the context of quantum chemistry, where issues such as improving the computational efficiency of determining electronic correlation energies are an ongoing endeavor [1, 2]. Solutions to problems of this nature are highly desirable, yet finding them is notoriously computationally challenging, and far beyond the capabilities of even the most powerful of present-day supercomputers. Researchers have tried to mitigate this issue of intractability by implementing heuristics and approximation techniques such as density functional theory (DFT) in attempts to decrease the computational cost of simulating more complex molecular systems [3, 4]. Nevertheless, even state-of-the-art approaches such as the employment of coupled-cluster techniques are met with considerable limitations, as they can accurately handle, at most, molecules of a few dozen atoms in size [5, 7]. Essentially, the common obstacle that these techniques all share can be understood as an established trade-off between the computational efficiency of the solver, and the accuracy of the obtained approximate solution.

As a promising initiative to alleviate this issue and reduce the resources required, there has been increasing interest in solving quantum problems using quantum devices [8–10]. These methods stand to offer a more scalable alternative that would help circumvent the limitations currently imposed by classical computation. However, the main challenge faced in the near term for quantum devices is the absence of error correction techniques [11]: without proper error corrections, computational results may not be reliable due to qubit decoherence and control errors. Two ways to overcome drawbacks of this nature that present themselves in the absence of error correction is therefore to shorten the time taken to perform a single run of a quantum algorithm, and to make the computational process as noise resilient as possible. One way to achieve these aims is by employing variational methods [12–14] using shallow circuit ansatz (e.g., see [15–17]) in quantum–classical hybrid algorithms.

In this paper, we consider the adiabatic approach of quantum computation for solving the problem of finding eigenstates. Adiabatic state preparation as a computational approach offers many desirable features, such as robustness against various types of noise [18–22], the absence of Trotterization errors, and the absence of accuracy limitations that arise from the requirement of having highly complicated ansatz. Despite these advantages, there remain factors that influence the choice of the annealing time $T$ that can affect the accuracy of the obtained results.

In ASP, if $T$ is defined to be too small, one subjects the system to the potential of undergoing harmful non-adiabatic transitions, and as a result the computation...
becomes susceptible to finding inaccurate results. Conversely, selecting too large a value of \( T \) can result in the loss of quantum information due to decoherence. The major challenge of near-term devices is that decoherence may occur quite early—before the adiabaticity condition is met—the consequence of which is that we obtain an inaccurate result.

Therefore, the main objective of this work is to develop an algorithm in which \( T \) can be chosen small enough to avoid decoherence, while simultaneously avoiding harmful non-adiabatic transitions. Based on previous works \cite{14, 23}, we consider a variational method to achieve this objective.

In the context of molecular systems, it was successfully demonstrated that a significant reduction in the required annealing time per individual run was achieved to a degree of accuracy within a certain threshold, compared to the standard ASP method \cite{23}.

This was achieved by initializing a set of new terms, denoted the “navigator Hamiltonian”, during the annealing schedule. Each respective Hamiltonian involved in the computation—the initial Hamiltonian, navigator Hamiltonian, and final Hamiltonian—was assigned a predetermined scheduling function, similar to the settings employed in \cite{14, 24, 26}. Additionally, the coefficients of the defining terms present in both the navigator Hamiltonian and the initial Hamiltonian were defined variationally. It is worth noting that in the case of molecular systems investigated in \cite{23}, the reduction in annealing time required to achieve a specified accuracy was enabled in part by accessing excited states during annealing.

A natural consequence of utilizing this variational technique towards establishing the schedule functions is that the accuracy of the obtained quantum state is highly dependent on the schedule functions of the Hamiltonians involved. Therefore, finding optimal schedule functions is essential in investigating whether quantum annealing can provide an advantage in solving combinatorial optimization problems. Various forms of schedule functions have been considered both theoretically and experimentally. Examples include the inhomogeneous transverse field \cite{27, 30}, which is characterized by individual qubits possessing distinct transverse field strengths; the anneal “pause and quench” schedule \cite{31, 32}, where the scheduling functions are held constant for a certain period of time followed by a rapid modification; and reverse annealing \cite{23, 33, 38}, which operates by starting a system in a classical state, introduces quantum fluctuations, and finally terminates by the removal of these fluctuations.

The variational method we present in this paper incorporates these ideas to solve more general problems within a shortened annealing time per individual iteration. We investigate the efficiency of the method in two contexts, the first being a quantum chemistry problem and the second an optimization problem.

The structure of the paper is as follows. In Sec. II, we explain the variationally scheduled quantum simulation algorithm (VSQS). In Sec. III, we demonstrate the efficiency of VSQS in solving the eigenstates problem for the hydrogen and P4 molecular systems. In Sec. IV, we apply VSQS in solving the Ising model. In Sec. V, we study how control error is mitigated in VSQS by implementing an inaccurate final Hamiltonian into the algorithm’s parameters. We conclude our work with a summary of our analysis in Sec. VI.

II. THE VARIATIONALLY SCHEDULED QUANTUM SIMULATION ALGORITHM

In the case of standard ASP, the time-dependent Hamiltonian \( H \) has both a fixed initial Hamiltonian \( H_{ini} \) and final Hamiltonian \( H_{fin} \), as well as their predetermined schedule functions \( A(t) \) and \( B(t) \), respectively:

\[
H = A(t)H_{ini} + B(t)H_{fin}
\]

For a given annealing time \( T \), the coefficients \( A(t) \) and \( B(t) \) satisfy the following boundary conditions: \( A(0) = B(T) = 1 \) and \( A(T) = B(0) = 0 \). In the case of quantum annealing techniques that target Ising models, the Hamiltonian \( H_{ini} \) is usually taken to be a summation of the transverse field for all the qubits: \( H_{ini} = \sum_i \sigma_i^x \). In recent years, the efficiency of quantum annealing for more-general functions has been investigated. One approach is to increase the flexibility of the functions \( A(t) \) and \( B(t) \) themselves. Instead of monotonically and smoothly changing functions, non-monotonic or non-smooth functions are considered \cite{23, 31, 38}.

The approach that we implement in VSQS is to find the optimal scheduling functions variationally by using a quantum–classical hybrid method. Let us first consider the case where \( H_{ini} \) and \( H_{fin} \) both have a single coefficient each, \( A(t, a) \) and \( B(t, b) \):

\[
H(t, a, b) = A(t, a)H_{ini} + B(t, b)H_{fin}
\]

The schedule functions \( A \) and \( B \) are defined using variational parameters \( a = (a_1, a_2, \ldots) \) and \( b = (b_1, b_2, \ldots) \). As one example of defining the functions by using variational parameters, we split the annealing time \( T \) into \( S \) intervals, \( (i-1)T/S < t < iT/S \), \( i \in [1, S] \). At the end of the \( i \)-th interval, the schedule functions \( A \) and \( B \) take parameters \( a_i \) and \( b_i \), after which they are linearly interpolated in the intervals:

\[
A(t, a) = \frac{a_i - a_{i-1}}{T/S} \left( t - (i-1)\frac{T}{S} \right) + a_{i-1}
\]

\[
B(t, b) = \frac{b_i - b_{i-1}}{T/S} \left( t - (i-1)\frac{T}{S} \right) + b_{i-1}
\]

In the above equations, the parameters \( a_0 = b_S = 1 \) and \( a_S = b_0 = 0 \) in order to satisfy the required boundary conditions. Therefore, we do not treat them as variational parameters. Another example of the schedule function has only two values, 0 and 1, where the duration of each operation is determined variationally. This so-called “bang-bang” control procedure is known to be optimal in
the case of classical systems, according to Pontryagin’s principle. However, the bang-bang control technique may or may not be optimal for quantum systems under certain conditions [29, 40].

The structure of VSQS is shown in Fig. 2 To run VSQS, we first generate an initial set of the variational parameters \((a^{0}(0), b^{0}(0))\), and subsequently perform the parametric ASP \(H(t, a^{0}(0), b^{0}(0))\),

\[
|\psi(T, a^{0}(0), b^{0}(0))\rangle = \mathcal{T} \exp \left( -i \int_0^T H(t, a^{0}(0), b^{0}(0))dt \right) |\psi(0)\rangle,
\]

where \(\mathcal{T}\) represents the time ordering operator. From the generated quantum state, the expectation value of the final Hamiltonian, \(E = \langle H_{\text{fin}} \rangle\), is obtained via measurement. In the case of combinatorial optimization problems, \(H_{\text{fin}}\) is a function of \(\sigma^z\) only; therefore, one measurement is sufficient for an adequate evaluation of the energy. On the other hand, in the case of quantum problems, terms in \(H_{\text{fin}}\) do not necessarily commute with each other, and the ground state of \(H_{\text{fin}}\) is therefore not an eigenstate of any individual term. As a consequence, we need to measure the expectation value of each operator by repeatedly preparing the state. It is worth mentioning that terms that qubit-wise commute with each other can be evaluated at the same time. Notably, various devices allow measurements to be performed only in the computational basis. Thus, in order to measure terms containing \(\sigma^z\) or \(\sigma^y\), single-qubit rotations for the corresponding qubits need to be performed at the end of the annealing process so that the term to measure becomes a tensor product of \(\sigma^z\) and the identity operator \(I\). Recall that the expectation value \(\langle H_{\text{fin}} \rangle\) is a function of variational parameters, and therefore optimal variational parameter values must be chosen. The data representing the obtained energy and the variational parameters are sent as input to a classical optimizer, which then updates the values \((a^{1}(0), b^{1}(0))\). Quantum annealing is performed based on the updated values \((a^{1}(0), b^{1}(0))\), and the calculations are iterated until the convergence condition of the energy has been satisfied.

Another example implementation of VSQS we consider is one that provides an independent schedule function for each term. In employing quantum annealing to target Ising problems, in contrast to using a single coefficient \(A(t)\) for all of the transverse fields, we instead consider the qubit-dependent coefficient \(A_i(t)\):

\[
H = \sum_i A_i(t) \sigma_i^z + B(t) H_{\text{fin}}
\]

This type of protocol is commonly denoted “inhomogeneous transverse field scheduling”, or “annealing offset scheduling”. Theoretical research has suggested that dramatic improvements in the likelihood of success can be accomplished by applying qubit-independent transverse fields [27, 39]. To extend this idea toward solving more-general problems, one can employ term-dependent scheduling in VSQS. To achieve this, let us write

\[
H_{\text{ini}} = \sum_{i=1}^{M_{\text{ini}}} J_i \sigma_i^{\text{ini}}, \quad H_{\text{fin}} = \sum_{j=1}^{M_{\text{fin}}} J_j \sigma_j^{\text{fin}},
\]

where \(M_{\text{ini}}\) and \(M_{\text{fin}}\) are the numbers of terms in \(H_{\text{ini}}\) and \(H_{\text{fin}}\), respectively, \(\sigma^i\) is a tensor product of Pauli matrices, and \(J_i, J_j\) are coefficients. In VSQS, the time dependence of each term is defined by the variational parameters \(a_i, b_j\):

\[
H = \sum_{i=1}^{M_{\text{ini}}} A_i(t, a_i) J_i \sigma_i^{\text{ini}} + \sum_{j=1}^{M_{\text{fin}}} B_j(t, b_j) J_j \sigma_j^{\text{fin}}.
\]

Note that some of the coefficients can be the same function, for example, \(a_i = a_j\) for some \(i \neq j\). This reduces the number of variational parameters and therefore reduces the computational cost of the classical optimizer. In what follows, we consider distributing \(\sigma_i^{\text{ini}}\) and \(\sigma_j^{\text{fin}}\) into \(I\) and \(F\) groups, respectively, and give each group an independent schedule function.

Finally, we consider the addition of terms to VSQS. While it is standard to choose the final Hamiltonian as the problem Hamiltonian in whose ground state we are interested, there is no restriction in what kind of terms are switched on during annealing. In [14, 23, 26], the additional terms were introduced in order to improve computational performance. We call the set of additional terms a navigator Hamiltonian \(H_{\text{nav}}\). The only condition that must be satisfied is that the schedule function of \(H_{\text{nav}}\) is zero at both the beginning and the end of the annealing process,

\[
H(t, a, b, c) = A(t, a) H_{\text{ini}} + B(t, b) H_{\text{fin}} + C(t, c) H_{\text{nav}},
\]

with \(C\) satisfying the boundary conditions \(C(0) = C(T) = 0\), and a nontrivial choice of \(H_{\text{nav}}\). In [23], \(H_{\text{nav}}\) was chosen to be a cluster operator that

![FIG. 1. Variationally determined time dependence](image)
was used in either the unitary coupled-cluster (UCC) or generalized unitary coupled-cluster (GUCC) method. In example combinatorial optimization problems, non-standard quantum fluctuations such as $\sigma_i^z \sigma_j^z$ interactions were used as navigator Hamiltonians [26, 41–48].

III. APPLICATION TO MOLECULAR SYSTEMS

A. Hydrogen molecule

We demonstrate the efficiency of VSQS within the context of determining the ground states of various molecular systems via a direct comparison with results obtained using the standard ASP approach. The number of variational parameters used in the algorithm are determined by the split number of the annealing time $(S)$, the group number of the initial Hamiltonian $(I)$, and the group number of the final Hamiltonian $(F)$. As an initial example, we consider a hydrogen molecule, whose Hamiltonian takes the form

$$H_{\text{fin}} = f_0 + f_1(\sigma_i^z + \sigma_j^z) + f_3\sigma_i^z\sigma_j^z + f_4\sigma_i^+\sigma_j^\dagger,$$

where we use the Bravyi–Kitaev transformation [49] of the second quantized Hamiltonian and remove two qubits based on the conservation of the spin symmetries [50, 51]. As this is a two-qubit problem with only $\sigma_i^z \sigma_j^z$ and $\sigma_i^+ \sigma_j^\dagger$ two-qubit couplings, it is feasible for this model to be implemented on a hardware platform such as [52]. More general chemical problems usually possess higher-order couplings, and in such cases the use of perturbative gadgets to reduce these higher-order couplings to two-qubit couplings may be required. For more detail on such cases, see [53–57]. The initial Hamiltonian for the system is taken as the Hartree–Fock Hamiltonian

$$H_{\text{ini}} = g_1(\sigma_i^z + \sigma_j^z).$$

In order to see the roles played by time splitting and grouping terms in VSQS, we study three different cases of the split number, the initial group number, and the final group number: $(S, I, F) = (2, 1, 1)$, $(5, 1, 1)$, and $(5, 2, 4)$. In the case of $(S, I, F) = (2, 1, 1)$ or $(5, 1, 1)$, we do not split the terms in the initial and the final Hamiltonians. In this sense, they are homogeneous. The split number $S = 2$ is the simplest nontrivial schedule and $S = 5$ has more flexibility. In the case of $(S, I, F) = (5, 2, 4)$, the number of $I$ and $F$ are chosen to equal the maximum: the number of terms in the initial Hamiltonian is 2 and that of the final Hamiltonian, except the term proportional to the identity, is 4. In this sense, it is maximally inhomogeneous. For $(S, I, F) = (2, 1, 1)$ and $(5, 1, 1)$, the time-dependent Hamiltonian is given by

$$H = A(a_i)H_{\text{ini}} + B(b_i)H_{\text{fin}},$$

with $i = 1$ and $i \in [1, 4]$ for $(2, 1, 1)$ and $(5, 1, 1)$, respectively. For $(5, 2, 4)$, all terms have the unique time dependence

$$H = \sum_{k=1}^{2} A_k(a_i)\sigma_k^z + \sum_{j=1}^{4} B_j(b_i)\sigma_j^z,$$

where $\sigma_i = \{\sigma_i^x, \sigma_i^y, \sigma_i^z, \sigma_i^+\sigma_i^\dagger, \sigma_i^z\sigma_i^z\}$. The nuclear separation distance is chosen to be $d = 1$ Å, and the amplitudes $|A_k|$ and $|B_k|$ are bounded by the value 10. To set the range for the variational parameters, we use the limited-memory Broyden–Fletcher–Goldfarb–Shanno method for bound-constrained optimization (L-BFGS-B) as an optimizer. The main purpose of this constraint in the amplitude of the variational parameters is to avoid a large deviation in the norm of the Hamiltonian from the one for standard ASP. As a comparison, standard ASP is considered with
the schedule functions
\[ A(t) = 1 - \left( \frac{t}{T} \right)^2, \quad B(t) = \left( \frac{t}{T} \right)^2. \] (13)

The obtained energy as a function of the annealing time \( T \) is shown in Fig. 3. The tolerance of the optimizer is set to \( 10^{-6} \). The optimizer converges between 50–75 iterations for \( T < 0.5 \) and 25–50 iterations for \( T > 0.5 \). As a measure of the accuracy of the result, we use the chemical accuracy (1 kcal/mol). The adiabatic theorem guarantees that the result will converge to the exact result as the annealing time \( T \) is taken to be large in the absence of noise and errors. We consider annealing time \( T \) as a measure of the accuracy of the result, we use the standard ASP and achieves chemical accuracy at \( T_{\text{CA}} \approx 1.1 \). On the other hand, the obtained energies for the cases of amplitudes bounded by 10 and 100 are the same, and they suddenly drop from the Hartree–Fock energy to the exact energy at \( T_{\text{CA}} \approx 0.2 \). This shows that the optimal schedule functions are within the range of ±10 for the entire \( t \in [0, T] \) and an increase in the bound does not improve the performance. Notice that since we set boundary conditions for the amplitudes at \( t = 0 \) and \( T \), for a given set of group numbers, one cannot simply rescale the Hamiltonian to shorten the annealing time.

The numerical results show that in the example of a hydrogen molecule, there is no clear difference in accuracy between different groupings. In all three cases studied, the value of the energy drops rapidly from the Hartree–Fock energy to the exact energy at \( T_{\text{CA}} \approx 0.2 \). On the other hand, it decreases continuously in the case of standard ASP and achieves chemical accuracy at \( T_{\text{CA}} \approx 12.9 \).

Next, we study the dependence of accuracy on the amplitude. For a fixed group number \((5,1,1)\), we change the upper bound of the amplitudes. The main objective is to understand whether the achievement of the shorter annealing time is due to the large amplitude of the Hamiltonian. We study three upper bounds: 1, 10, and 100. The obtained energy as a function of the annealing time is shown in Fig. 4. For the case of the amplitude with a bound of 1, the energy decreases smoothly from the Hartree–Fock energy to the exact energy. The time to chemical accuracy is \( T_{\text{CA}} \approx 1.1 \). On the other hand, the obtained energies for the cases of amplitudes bounded by 10 and 100 are the same, and they suddenly drop from the Hartree–Fock energy to the exact energy at \( T_{\text{CA}} \approx 0.2 \). This indicates that the annealing process uses non-adiabatic transitions to reach accurate results in a shorter time than expected from the adiabatic condition. See, for instance, \([58–61]\). In the case of VSQS, \( T_{\text{CA}} \) has a different dependence on \( d \) compared to the standard ASP case. It takes the maximum values between \( d = 2.8 \) and 3.0 for \((2,1,1)\) with \( T_{\text{CA}} \approx 0.7 \), whereas they are between \( d = 2.8 \) and 3.6 for \((5,1,1)\) and \((5,2,4)\) with \( T_{\text{CA}} \approx 0.32 \). \( T_{\text{CA}} \) is small for standard ASP for these distances due to the non-adiabatic transitions.

![Fig. 3. Obtained energy as a function of the annealing time T. The dotted green line, and the solid light-blue, dotted yellow, and solid blue lines are the results of standard ASP, and VSQE with \((S,I,F) = (2,1,1), (5,1,1),\) and \((5,2,4)\), respectively. The amplitudes \( |A_k| \) and \( |B_k| \) are bounded by 10.](image)

![Fig. 4. Obtained energy E as a function of the annealing time T. The dotted green line, and the solid light-blue, dotted yellow, and solid blue lines are the results of standard ASP, and VSQE with \((S,I,F) = (5,1,1)\) and the amplitudes bounded by 1, 10, and 100, respectively.](image)
FIG. 5. Time to chemical accuracy for H$_2$. The dotted green line, and the solid light-blue, dotted yellow, and solid blue lines are the results of standard ASP, and VSQE with $(S, I, F) = (2, 1, 1)$, $(5, 1, 1)$, and $(5, 2, 4)$, respectively.

B. P4 molecule

The second example system we investigate is P4, a system of two hydrogen molecules with bonds lying parallel to each other. In particular, we choose a square configuration where each hydrogen atom is located at the vertex and each edge has a distance 2 Å. One motivation for considering this system is that it is difficult to obtain an accurate energy value with this configuration because of degeneracy. It was shown in [23] that both the classical method with coupled-cluster singles and doubles (CCSD), and the variational quantum eigensolver (VQE) with unitary coupled-cluster singles and doubles (UCCSSD), fail to achieve chemical accuracy. We study the performance of VSQS for the fixed amplitude bounds $|A_1|, |B_1| \leq 10$. Three choices for the group numbers $(S, I, F) = (2, 1, 1)$, $(5, 1, 1)$, and $(5, 6, 10)$ are considered. The results are shown in Fig. 6. In standard ASP (shown using a dotted green line), the energy decreases monotonically as a function of the annealing time. It requires $T \geq 456$ to achieve chemical accuracy. For all the cases using the variational method, the energy decreases much faster than with standard ASP. However, the details of the decrease in energy is different from the case of hydrogen. For the hydrogen molecule, there was no difference despite the choice of group number. However, the difference is clear in the case of P4. The group number $(5, 1, 1)$ provides a more stable configuration compared to $(2, 1, 1)$. Therefore, the increase of the split number is important. Moreover, the result for the group number $(5, 6, 10)$ reaches chemical accuracy around $T_{CA} \simeq 9$, whereas those of $(2, 1, 1)$ and $(5, 1, 1)$ plateau for a certain range of $T$ before achieving chemical accuracy around $T_{CA} \simeq 133$ and $T_{CA} \simeq 23$, respectively.

IV. ISING MODEL

We now apply VSQS for solving an Ising model problem. As an example, we consider a triangular lattice, shown in Fig. 7. Each vertex (shown using a light-blue circle) represents a qubit, each solid dark-blue line (within the upper layer or lower layers) represents antiferromagnetic coupling ($J^{AF} > 0$), and each edge of dashed red line (inter-layer) represents a ferromagnetic coupling ($J^F < 0$). The values of the ferromagnetic and antiferromagnetic couplings are randomly generated:

$$H_{\text{fin}} = \sum_{(i,j) \in \text{Intralayer}} J^{AF}_{ij} \sigma^z_i \sigma^z_j + \sum_{(k,l) \in \text{Interlayer}} J^F_{kl} \sigma^z_k \sigma^z_l$$

(14)

We consider the following Hamiltonian:

$$H = A(t)H_{\text{ini}} + B(t)H_{\text{fin}} + \sum_{(i,j) \in \text{Edges}} C_{ij}(t) \sigma^z_i \sigma^z_j$$

(15)

We take $M_{\text{ini}} = M_{\text{fin}} = 1$ while all the terms in $H_{\text{nav}}$ have independent time dependence. We choose the split numbers to be 2 and 5.

First, we look at the case where $S = 5$. Figure 8 shows the success probability of standard ASP and VSQS as a function of the annealing time $T$. In the standard ASP case, the success probability remains close to zero until $T \sim 10$, then begins to increase. At $T \sim 116$, the success probability reaches 0.99. On the other hand, in VSQS, the probability is greater than 0.99 even when the annealing time is as short as 0.01.

Figure 9 and Fig. 10 show the optimal schedule functions $\{A(t), B(t), C_{ij}(t)\}$ for $T = 0.1$ and $T = 2.0$, respectively. The solid red line represents the coefficient $A(t)$
FIG. 7. Triangular lattice. Circles represent qubits, and the solid dark-blue and the dashed red lines represent antiferromagnetic and ferromagnetic couplings, respectively.

FIG. 8. Success probability \( p \) of standard ASP and VSQS for the triangular lattice Ising model of \( H_{\text{ini}} \), and the solid green line represents the coefficient \( B(t) \) of \( H_{\text{fin}} \). The dashed light-blue lines represent the coefficients \( C_{ij}(t) \) of the terms in \( H_{\text{nav}} \). At \( T = 0.1 \), two couplings in \( H_{\text{nav}} \) become large during annealing, while the others remain small. As the annealing time increases, all the schedule functions take values within a small parameter region. The schedule functions \( C_{ij}(t) \) fluctuate between both positive and negative values. This means that the Hamiltonian is non-stoquastic.

Our motivation for using the variational method is to obtain accurate results despite the fact that quantum devices are noisy. Therefore, we have focused on the annealing time per individual run thus far. We also study the total annealing time in the variational approach. Let us first consider standard ASP. We denote the success probability at an annealing time \( T_{\text{stand}} \) as \( p_{\text{stand}}(T_{\text{stand}}) \). By repeating the same calculation \( N_{\text{stand}} \) times, one can increase the success probability using the expression 
\[
1 - (1 - p_{\text{stand}}(T_{\text{stand}}))^{N_{\text{stand}}}
\]
with the total computational time \( T_{\text{stand}}N_{\text{stand}} \).

In the case of VSQS, we must first iterate the performed calculations to optimize variational parameters. Let us denote the number of iterations for optimizing the variational parameters by \( N_{\text{VSQS}}^{\text{opt}} \), and the annealing time per individual run by \( T_{\text{VSQS}} \). In the case of variational methods, including a quantum approximate optimization algorithm (QAOA) [62], which uses expectation values of the Hamiltonian to adjust variational parameters, one needs to repeat a given calculation in order to reduce statistical errors. We denote the repetition number for obtaining an expectation value of a Hamiltonian by \( M \). Having \( N_{\text{VSQS}}^{\text{opt}} \) iterations of the optimization process requires \( N_{\text{VSQS}}^{\text{opt}}M \) repetitions on a quantum device. The success probability of an individual run at \( T_{\text{VSQS}} \) is denoted by \( p_{\text{VSQS}}(T_{\text{VSQS}}) \). Then, by repeating the calculation \( N_{\text{VSQS}}^{\text{add}} \) times with fixed variational parameters, we can obtain the correct answer with a success probability of 
\[
1 - (1 - p_{\text{VSQS}}(T_{\text{VSQS}}))^{N_{\text{VSQS}}^{\text{add}}}
\]
and with a total annealing time of \( T_{\text{vs}}(N_{\text{VSQS}}^{\text{opt}}M + N_{\text{VSQS}}^{\text{add}}) \). The change of the success probability as a function of iterations \( N_{\text{VSQS}}^{\text{opt}} \) is given in Fig. 11. We choose \( S = 2 \) and consider random values taken from the interval \([-1, 1]\) for the initial variational parameters \( C_{ij} \). The group number for the navigator Hamiltonian is 7. One of the main differences between a quantum chemistry problem and a combinatorial optimization problem is that it is not necessary for the com-
binomial optimization problem to achieve very high accuracy for a single run. So long as the success probability for a single run is reasonably high, one can increase the success probability quickly by repeating the calculations. Therefore, we choose a loose tolerance for the optimization: $tol = 1.0$. We use the constrained optimization by linear approximation (COBYLA) algorithm. We see that the success probability increases within a relatively small number of iterations for annealing times $T_{VSQS} = 0.1$ and 1.0. For instance, for $T_{VSQS} = 1.0$, the optimization converges to 0.759 after 24 iterations; for $T_{VSQS} = 0.1$, the optimization converges to 0.985 after 71 iterations; and for $T_{VSQS} = 0.01$, the optimization converges to 1.0 after 434 iterations. Therefore, the total annealing time needed to find the correct result with a success probability of 99% is $4.34M$ for $T_{VSQS} = 0.01$, $7.2M + 0.1$ for $T_{VSQS} = 0.1$, and $24M + 4$ for $T_{VSQS} = 1.0$ (i.e., 4 iterations after the optimization converges). For reference, the total annealing time needed for standard ASP to achieve a success probability of 99% is $T_{stand} = 116$.

V. SYSTEMATIC CONTROL ERROR

To date, many experiments (for instance, [12] [13] [51]) have demonstrated that the variational quantum eigensolver (VQE) is robust against systematic control errors. In VQE, quantum circuits are characterized by variational parameters. When the quantum gates over-rotate or under-rotate qubits due to inaccurate control, a classical optimizer finds different input angles that lead to more-accurate qubit rotations on quantum devices.

In ASP, a critical control error may occur in the couplings of the final Hamiltonian $H_{fin}$. In the ideal case, the quantum state reaches the ground state of $H_{fin}$ at the end of the annealing process. However, without error correction, the couplings on a quantum device may be degraded by control errors. In that case, the final state will be a ground state of an inaccurate Hamiltonian. Some approaches, such as using a non-vanishing value of either temperature or the transverse field, were considered in order to improve the success probabilities of quantum annealing [63] [64].

In this section, we investigate whether VSQS is capable of correcting such errors. One approach is to make the final Hamiltonian variational. Let us describe the accurate final Hamiltonian in terms of its components: $H_{fin} = \sum_i J_i \sigma_i^{fin}$. In the presence of control errors, the couplings of the final Hamiltonian on a quantum device have different values, which we denote by

$$H_{fin} = \sum_i J_i \sigma_i^{fin}.$$  \hspace{1cm} (16)

One way to use the variational method for mitigating systematic control errors is to treat the final Hamiltonian as variational. Starting from $J_i^{(0)} = J_i$ as input couplings, one runs a time-dependent Hamiltonian $H(t) = A(t)H_{ini} + B(t)H_{fin}$, measures the expectation values of the Pauli words $\langle \sigma_i^{fin} \rangle$, and then estimates the energy using the accurate coefficients $E = \sum_i J_i (\sigma_i^{fin})$. Based on the result, a classical optimizer updates $J_i^{(k-1)} \rightarrow J_i^{(k)}$ so that the couplings on the quantum device $\tilde{J}_i^{(k)}$ become closer to the accurate values $J_i$.

As an alternative method, we can use a non-adiabatic process to obtain accurate results. In this case, we fix the final Hamiltonian, and adjust the scheduling during the annealing process so that the final quantum state becomes closer to the exact ground state. Let us consider the following time-dependent Hamiltonian in VSQS:

$$H(t) = A(t)H_{ini} + B(t)H_{fin} + \sum_i C_i(t) \sigma_i^{fin}.$$ \hspace{1cm} (17)

The last term in Eq. (17) is the navigator Hamiltonian of GUCC that was used in [23]. Note that in the VSQS setting, one can absorb $B(t)$ into $C_i(t)$ by changing the boundary condition for $C_i(t)$, as the Pauli words in the second term and the third term in Eq. (17) are the same. Here, we treat $B(t)$ and $C_i(t)$ separately for the purpose of analyzing the contributions of the navigator Hamiltonian and the final Hamiltonian. As before, running the time-dependent Hamiltonian, the expectation values of each of the Pauli words $\langle \sigma_i^{fin} \rangle$ are measured. Then, the total energy is calculated by using the accurate coefficients $E = \sum_i J_i (\sigma_i^{fin})$. It is this quantity $E$ that an optimizer on a classical computer minimizes. This optimization process works as it is the ground state of $H_{fin} = \sum_i J_i \sigma_i^{fin}$ that minimizes the function $\sum_i J_i (\sigma_i^{fin})$.

To demonstrate this method, we consider the hydrogen molecule. We add Gaussian noise to the coefficients

$$\tilde{J}_i = J_i + \xi_i,$$ \hspace{1cm} (18)

where $\xi_i \in \mathcal{N}(\alpha, \beta)$, with $\alpha$ and $\beta$ being the mean and
the standard deviation, respectively. We estimate the energy using different noise values $\xi_i$ for both standard ASP and VSQS. A histogram of obtained energies is shown in Fig. 12. For both standard ASP and VSQS, the annealing time is chosen to be long enough to reach chemical accuracy when the accurate Hamiltonian $H_{\text{fin}}$ is used: $T = 20$ for standard ASP and $T = 1$ for VSQS. Two distributions representing the control errors are considered; one has a zero mean $\mathcal{N}(0, 0.1)$ and the other has a non-zero mean $\mathcal{N}(0.2, 0.2)$. As shown in Fig. 12, the obtained energy in standard ASP has a wide range of distribution in $E$. This is expected, as standard ASP generates a ground state of the inaccurate Hamiltonian $\tilde{H}_{\text{fin}} = \sum_i \tilde{J}_i \sigma_i$. On the other hand, in VSQS, the obtained energies always remain within chemical accuracy. Therefore, we conclude that VSQS has resilience against control errors.

**VI. CONCLUSION**

In this paper, we proposed performing quantum simulations using variationally determined schedule functions. Our main objective was to shorten the time of individual runs during iterations of annealing, which is essential for obtaining accurate results in the absence of error correction. We conducted numerical simulations with the intent of investigating several characteristics of the VSQS algorithm by using the examples of finding ground states of molecular systems ($H_2$ and P4) and Ising model. We analyzed the effects and advantages gained by the introduction of distinct schedule functions for distinct spins and optimizing the schedule functions variationally.

For computationally simple problems, such as finding the ground state of a hydrogen molecule, the optimization of the schedule functions enabled us to shorten the time of a single annealing run significantly. For more challenging problems, namely the square configuration of the P4 molecule in which the highest occupied and lowest unoccupied molecular orbitals become degenerate, the use of distinct schedule functions for distinct terms is more important for shortening the annealing time.

We also applied the VSQS algorithm for the triangular Ising model, which has randomness and frustration. In this model, we introduced a navigator Hamiltonian consisting of $\sigma^x \sigma^x$ couplings. We found that the time-dependent Hamiltonian becomes non-stoquastic for the optimal schedule functions.

Furthermore, we demonstrated the VSQS algorithm’s resilience to control errors. We considered the case where the final Hamiltonian was inaccurately implemented. When the quantum state followed the adiabatic path, then the final state became the ground state of the inaccurate final Hamiltonian. Therefore, the computational results provide inaccurate answers for optimization problems. The VSQS algorithm allows for adjustments to be made to the schedule functions so that the final state minimizes the accurate Hamiltonian instead of the inaccurate Hamiltonian. By doing so, we successfully generated the true ground state of a hydrogen molecule.

**VII. ACKNOWLEDGEMENT**

We thank Marko Bucyk for reviewing and editing the manuscript.
Appendix A: Geometry of the P4 molecule

Figure 13 shows the geometry of the P4 molecule. The internuclear and intermolecular distances are chosen to be 2 Å.

FIG. 13. P4 molecule. The spheres represent hydrogen atoms.

Appendix B: Standard ASP results for the hydrogen molecule

The results of running standard ASP for the hydrogen molecule are shown in Fig. 14. The energy values exhibit non-monotonic behaviour as a function of the annealing time $T$ for $d = 2.5$ Å and $d = 3.0$ Å. This is evidence of coherent oscillation between different energy levels. See, for instance, [58–61].
